# Planning and Scheduling by Logic-Based Benders Decomposition

J. N. Hooker

Tepper School of Business, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213,  
john@hooker.tepper.cmu.edu

We combine mixed-integer linear programming (MILP) and constraint programming (CP) to solve an important class of planning and scheduling problems. Tasks are allocated to facilities using MILP and scheduled using CP, and the two are linked via logic-based Benders decomposition. Tasks assigned to a facility may run in parallel subject to resource constraints (cumulative scheduling). We solve problems in which the objective is to minimize cost, makespan, or total tardiness. We obtain significant computational speedups, of several orders of magnitude for the first two objectives, relative to the state of the art in both MILP and CP. We also obtain better solutions and bounds for problems than cannot be solved to optimality.

*Subject classifications:* integer programming; Benders decomposition; production/scheduling: planning.

*Area of review:* Optimization.

*History:* Received August 2004; revision received May 2006; accepted May 2006.

## Introduction

We address a fundamental planning and scheduling problem that occurs frequently in manufacturing and supply chain contexts. Tasks must be assigned to facilities and scheduled on each facility, subject to release dates and deadlines. Some of the tasks assigned to a given facility may run in parallel if desired, provided the total resource consumption at any time remains within limits (cumulative scheduling). Precedence and other side constraints may be imposed. The objective is to minimize cost, makespan, or total tardiness.

Although problems of this sort arise often, they have proved to be quite difficult to solve. In the absence of an effective formal algorithm, a common-sense approach is often used in practice. The problem is decomposed into an assignment portion and a scheduling portion. Central managers assign tasks to facilities, whereupon operations managers develop detailed schedules for the tasks assigned to each facility. Because the schedule for one or more facilities may prove infeasible or otherwise unsuitable, the schedulers may telephone headquarters and ask for a different allocation of tasks. The give-and-take continues until a mutually satisfactory solution is reached. However, an informal process of this sort is time consuming, and even if carried to completion offers no guarantee of obtaining a good solution.

One possibility that suggests itself is to apply Benders decomposition, which mimics the informal feedback loop in a rigorous fashion. The Benders master problem allocates tasks to facilities, and the subproblem separates into several independent scheduling problems. Benders cuts added to the master problem are a mathematical equivalent

of telephone calls from the operations managers. Under typical conditions, the Benders algorithm terminates with an optimal solution of the overall allocation and scheduling problem.

The classical Benders approach (Benders 1962, Geoffrion 1972) is inappropriate for this problem, however, because it requires that the subproblem be a continuous linear or nonlinear programming problem. Scheduling is a highly combinatorial problem that has no practical linear or nonlinear programming model. Fortunately, the idea of Benders decomposition can be extended to a logic-based form that accommodates an arbitrary subproblem, such as a discrete scheduling problem. This paper explores how a logic-based Benders method can be applied to planning and scheduling problems.

An additional advantage of logic-based Benders is that it permits one to exploit the relative strengths of mixed-integer linear programming (MILP) and constraint programming (CP). MILP is a natural approach to the allocation task of the master problem, and CP provides an effective scheduling technology that can be applied to the subproblem. Logic-based Benders therefore unites MILP and CP in an integrated approach that obtains provably optimal solutions.

The planning and scheduling problem can be formulated entirely as a MILP problem, or entirely as a CP problem. However, these models are hard to solve. By linking MILP and CP, we obtained substantial speedups relative to the existing state of the art in both MILP (as represented by CPLEX) and CP (as represented by the ILOG Scheduler).

In particular, we obtained speedups of several orders of magnitude for minimum-cost and minimum-makespan

problems. This allowed us to solve larger instances to optimality than could be solved previously. For minimum-tardiness problems, the computational advantage of a Benders method is less, but nonetheless substantial. Although we were not able to solve significantly larger instances to optimality, we obtained much better solutions and better bounds on the optimal value, within a given amount of computation time, than provided by MILP and CP. One advantage of the Benders method is that it can be terminated at almost any point with a feasible solution and a lower bound on the optimal value (except in the case of the minimum-cost problems). The bound improves steadily as the algorithm runs.

Unlike classical Benders, logic-based Benders provides no standard scheme for generating Benders cuts. Cuts must be devised for each problem class, and a major goal of this paper is to show that this can be done for a variety of objective functions. Specifically, we develop Benders cuts for (a) minimum-cost problems in which cost is a function of the assignment alone; (b) minimum-makespan problems in which all tasks have the same release date; and (c) minimum total tardiness problems in which all tasks have the same release date. We also develop relaxations of the subproblem for inclusion in the master problem because this often proves important for good performance.

## 1. Previous Work

Classical Benders decomposition solves a problem by enumerating values of certain primary variables. For each set of values enumerated, it solves the subproblem that results from fixing the primary variables to these values. (In our case, the primary variables define the allocation of tasks to facilities.) Solution of the subproblem generates a Benders cut that the primary variables must satisfy in all subsequent solutions enumerated. The Benders cut is a linear inequality based on Lagrange multipliers obtained from a solution of the subproblem dual. The next set of values for the primary variables is obtained by solving the master problem, which contains all the Benders cuts so far generated. The process continues until the master problem and subproblem converge in value.

Logic-based Benders decomposition was introduced by Hooker and Yan (1995) in the context of logic circuit verification. The idea was formally developed by Hooker (2000) and applied to 0-1 programming by Hooker and Ottosson (2003). In logic-based Benders, the Benders cuts are obtained by solving the inference dual of the subproblem, of which the linear programming dual is a special case. The solution of the inference dual is a proof of optimality when the primary variables are fixed to their current values. The Benders cut is constructed by using this same proof to derive a valid bound on the optimal value when the primary variables take other values. Although logic-based Benders cuts can assume any form, in the present context they must be formulable as linear inequalities because the master problem is a MILP.

The application of logic-based Benders to planning and scheduling was proposed by Hooker (2000) and first implemented by Jain and Grossmann (2001). They applied the idea to minimum-cost planning and scheduling problems in which the subproblems are disjunctive scheduling problems in which tasks must be run one at a time, rather than cumulative scheduling problems. Harjunkoski and Grossmann (2002) extended this work to multistage problems. The Benders cuts are particularly simple in these cases because the subproblem is a feasibility problem rather than an optimization problem. A goal of the present paper is to show that a Benders approach can succeed for a variety of planning and scheduling problems in which the Benders cuts are less obvious. In particular, we (a) accommodate cumulative scheduling, and (b) develop Benders cuts for two additional objective functions for which the subproblem is an optimization problem. Preliminary results are presented in conference papers (Hooker 2004, 2005).

In related work, Hooker (2005) applied a Benders method to minimizing the number of late jobs. Chu and Xia (2005) solved the minimum-makespan problem by generating Benders cuts with the help of an integer programming model of the subproblem, but the speedups are substantially less than reported here.

Hooker (2000) observed that the master problem need only be solved once by a branching algorithm that accumulates Benders cuts as they are generated. Thorsteinsson (2001) showed that this approach, which he called *branch and check*, can result in substantially better performance on the Jain and Grossmann (2001) problems than standard logic-based Benders. We did not implement branch and check for this study because it would require hand coding of a branch-and-cut algorithm for the master problem, but we obtained substantial speedups without it.

Logic-based Benders methods have also been adapted to solving integer programming problems (Hooker and Ottosson 2003, Chu and Xia 2004) and the propositional satisfiability problem (Hooker 2000, Hooker and Ottosson 2003). Similar ideas have been applied to minimal dispatching of automated guided vehicles (Corréa et al. 2004), steel production scheduling (Harjunkowski and Grossmann 2001), real-time scheduling of computer processors (Cambazard et al. 2004), traffic diversion (Xia et al. 2004), batch scheduling in a chemical plant (Maravelias and Grossmann 2004), and polypropylene batch scheduling in particular (Timpe 2002). In all these applications (except integer programming), the subproblem is a feasibility problem.

Classical Benders decomposition can also be useful in a CP context, as shown by Eremin and Wallace (2001).

## 2. The Problem

The planning and scheduling problem may be defined as follows. Each task  $j \in \{1, \dots, n\}$  is to be assigned to a facility  $i \in \{1, \dots, m\}$ , where it consumes processing time  $p_{ij}$  and resources at the rate  $c_{ij}$ . Each task  $j$  has release time  $r_j$  and deadline  $d_j$  (viewed as a due date in tardiness problems). The tasks assigned to facility  $i$  must be given start

times  $s_j$  in such a way that the total rate of resource consumption on facility  $i$  is never more than  $C_i$  at any given time. If  $x_j$  is the facility assigned to task  $j$ , the problem may be written

$$\text{minimize } g(x, s)$$

$$\text{subject to } r_j \leq s_j \leq d_j - p_{x_j} \quad \text{for all } j, \quad (\text{a})$$

$$\sum_{j \in J_i} c_{ij} \leq C_i \quad \text{for all } i, t, \quad (\text{b})$$

where  $J_{it} = \{j \mid s_j \leq t < s_j + p_{x_j}\}$  is the set of tasks underway at time  $t$  in facility  $i$ . It is assumed that for each  $j$ ,  $c_{ij} \leq C_i$  for at least one  $i$ .

An important special case is that in which the scheduling problem on facility  $i$  is an  $m$ -machine scheduling problem, for which  $C = m$  and each  $c_{ij} = 1$ . For a one-machine (disjunctive) scheduling problem, we have  $C_i = 1$ .

Precedence and other side constraints may be added if desired. For instance, one may require that tasks  $j$  and  $k$  be scheduled on the same facility, and that task  $j$  precede  $k$ , by writing the constraints  $x_j = x_k$  and  $s_j + p_{x_j} < s_k$ .

We investigate three objective functions:

- *cost*, given by  $g(x, s) = \sum_j F_{x_j}$ , where  $F_{x_j}$  is the fixed cost of processing task  $j$  on facility  $i$ ;
- *makespan*, given by  $g(x, s) = \max_j \{s_j + p_{x_j}\}$ ; and
- *total tardiness*, given by  $g(x, s) = \sum_j (s_j + p_{x_j} - d_j)^+$ , where  $\alpha^+$  is  $\alpha$  if  $\alpha > 0$ , and 0 otherwise.

When the tardiness objective is used, the deadlines become due dates and constraint (a) becomes  $r_j \leq s_j$  for all  $j$ .

### 3. Constraint Programming Formulation

The problem can be written in a constraint programming fashion using the global constraints *element* and *cumulative*. Given a vector  $v$  of values, the constraint

$$\text{element}(y, v, u) \quad (2)$$

sets  $u$  equal to the  $y$ th component of  $v$ . Thus, one can implement an expression of the form  $v_y$  by replacing  $v_y$  with  $u$  and writing constraint (2).

If  $s = (s_1, \dots, s_n)$ , and similarly for  $p$  and  $c$ , the constraint

$$\text{cumulative}(s, p, c, C) \quad (3)$$

requires that tasks be scheduled at times  $s_1, \dots, s_n$  so that the total rate of resource consumption at any given time never exceeds  $C$ . Thus,  $\sum_{j \in J_t} c_j \leq C$  for all  $t$ , where  $J_t = \{j \mid s_j \leq t < s_j + p_{x_j}\}$  is the set of tasks underway at time  $t$ . The cumulative constraint is widely used for resource-constrained scheduling problems in which tasks can run simultaneously.

Constraint programming solvers rely heavily on efficient filtering or domain reduction algorithms for these and other constraints. The filtering algorithms remove from the

domain of each  $s_j$  some or all values that cannot be part of a solution satisfying the constraint.

The planning and scheduling problem now becomes

$$\text{minimize } g(x, s)$$

$$\text{subject to } r_j \leq s_j \leq d_j - u_j \quad \text{for all } j,$$

$$\text{element}(x_j, (p_{1j}, \dots, p_{mj}), u_j) \quad \text{for all } j, \quad (4)$$

$$\text{cumulative}((s_j \mid x_j = i), (p_{ij} \mid x_j = i),$$

$$(c_{ij} \mid x_j = i), C_i) \quad \text{for all } i,$$

where  $g(x, s)$  is the desired objective function and  $(s_j \mid x_j = i)$  denotes the tuple of start times for tasks assigned to facility  $i$ . The first and second constraints enforce the time windows, and the third enforces the resource constraint.

For purposes of computational testing, we formulated (4) using the high-level modeling language of OPL Studio. The formulation for the minimum-cost problem appears in Figure 1. Formulations for the other objectives are similar. The *assignAlternatives* and *setTimes* search options specify a branching method that results in substantially better performance than the default method.

### 4. Mixed-Integer Programming Formulation

The most straightforward MILP formulation discretizes time and enforces the resource capacity constraint at each

**Figure 1.** OPL Studio code for the CP version of a minimum cost problem.

```
[declarations]
scheduleHorizon = max(j in J) task[j].d;
DiscreteResource facility[i in I](C[i]);
AlternativeResources facilitySet(facility);
Activity scheduleTask[j in J];
minimize
  sum(j in J) cost[j]
subject to {
  forall(j in J)
    scheduleTask[j] requires(taskf[i,j].r) facilitySet;
  forall(j in J)
    forall(i in I)
      activityHasSelectedResource(scheduleTask[j],facilitySet,
        facility[i]) <=> scheduleTask[j].duration = taskf[i,j].p
        & cost[j] = taskf[i,j].F;
  forall(j in J) {
    scheduleTask[j].start >= task[j].r;
    scheduleTask[j].end <= task[j].d;
  };
  search {
    assignAlternatives;
    setTimes;
  };
}
```

*Notes.* Parameters  $r_j$ ,  $d_j$ ,  $p_{ij}$ , and  $F_{ij}$  are represented by  $task[j].r$ ,  $task[j].d$ ,  $taskf[i,j].p$ , and  $taskf[i,j].F$ , respectively. The resource limit  $C_i$  is  $C[i]$ . Index set  $J$  is  $\{1, \dots, n\}$  and  $I$  is  $\{1, \dots, m\}$ .

discrete time. Let the 0-1 variable  $x_{ijt} = 1$  if task  $j$  starts at discrete time  $t$  on facility  $i$ . The minimum-cost formulation is

$$\min \sum_{ijt} F_{ij} x_{ijt}$$

$$\text{subject to } \sum_{it} x_{ijt} = 1 \quad \text{for all } j, \quad (a)$$

$$\sum_j \sum_{t' \in T_{ijt}} c_{ij} x_{ijt'} \leq C_i \quad \text{for all } i, t, \quad (b)$$

$$x_{ijt} = 0 \quad \text{for all } j, t \text{ with } t \leq r_j \\ \text{or } t > d_j - p_{ij}, \quad (c)$$

where each  $x_{ijt}$  is a 0-1 variable.  $T_{ijt} = \{t' \mid t - p_{ij} < t' \leq t\}$  is the set of discrete times at which a task  $j$  in progress on facility  $i$  at time  $t$  might start processing. Constraint (a) ensures that each task starts once on one facility, (b) enforces the resource limit, and (c) the time windows. The minimum-makespan problem is

$$\begin{aligned} & \min M \\ \text{subject to } & M \geq \sum_{it} (t + p_{ij}) x_{ijt} \quad \text{for all } j, \\ & \sum_{it} x_{ijt} = 1 \quad \text{for all } j, \\ & \sum_j \sum_{t' \in T_{ijt}} c_{ij} x_{ijt'} \leq C_i \quad \text{for all } i, t, \\ & x_{ijt} = 0 \quad \text{for all } j, t \text{ with } t \leq r_j \\ & \text{or } t > d_j - p_{ij}. \end{aligned} \quad (6)$$

The minimum total tardiness problem is

$$\begin{aligned} & \min \sum_j T_j \\ \text{subject to } & T_j \geq \sum_{it} (t + p_{ij}) x_{ijt} - d_j \quad \text{for all } j, \\ & \sum_{it} x_{ijt} = 1 \quad \text{for all } j, \\ & \sum_j \sum_{t' \in T_{ijt}} c_{ij} x_{ijt'} \leq C_i \quad \text{for all } i, t, \\ & x_{ijt} = 0 \quad \text{for all } j, t \text{ with } t \leq r_j, \\ & T_j \geq 0 \quad \text{for all } j, \end{aligned} \quad (7)$$

where  $T_j$  is the tardiness of task  $j$ .

Models (5)–(7) can grow large due to time-indexed variables. We therefore investigated a smaller discrete-event model suggested by Türkay and Grossmann (1996) that uses continuous time. Given  $n$  tasks, there are  $2n$  events. The model decides, for each event, which task it is associated with, whether it is the start or end of the task, and when the task starts. Let the binary variable  $x_{ijk}$  be one when event  $k$  is the start of task  $j$  on facility  $i$ , and let  $y_{ijk}$  be one when event  $k$  is the end of task  $j$  on facility  $i$ . The

continuous variable  $s_{ik}$  is the start time of event  $k$  on facility  $i$  when the event is assigned to facility  $i$ . Continuous variable  $f_{ij}$  is the finish time of task  $j$  on facility  $i$  when task  $j$  is assigned to facility  $i$ . The disaggregation of the start- and finish-time variables allows the model to impose resource constraints.

The minimum-cost model is

$$\min \sum_{ijk} F_{ij} x_{ijk}$$

$$\text{subject to } \sum_{ik} x_{ijk} = 1, \quad \sum_{ik} y_{ijk} = 1 \quad \text{for all } j, \quad (a)$$

$$\sum_{ij} x_{ijk} + y_{ijk} = 1 \quad \text{for all } k, \quad (b)$$

$$\sum_k x_{ijk} = \sum_k y_{ijk} \quad \text{for all } i, j, \quad (c)$$

$$s_{i,k-1} \leq s_{ik} \quad \text{for all } i, k, \quad (d)$$

$$r_j x_{ijk} \leq s_{ik}, \quad f_{ij} \leq d_j \quad \text{for all } i, j, k, \quad (e)$$

$$\begin{aligned} & s_{ik} + p_{ij} x_{ijk} - M(1 - x_{ijk}) \\ & \leq f_{ij} \leq s_{ik} + p_{ij} x_{ijk} + M(1 - x_{ijk}) \\ & \quad \text{for all } i, j, k, \quad (f) \end{aligned}$$

$$\begin{aligned} & s_{ik} - M(1 - y_{ijk}) \leq f_{ij} \leq s_{ik} + M(1 - y_{ijk}) \\ & \quad \text{for all } i, j, k, \quad (g) \end{aligned}$$

$$R_{ik} \leq C_i \quad \text{for all } i, k, \quad (h)$$

$$\begin{aligned} R_{i1} &= R_{i1}^s, \quad R_{ik}^s = \sum_j c_{ij} x_{ijk}, \quad R_{ik}^f = \sum_j c_{ij} y_{ijk} \\ & \quad \text{for all } i, k, \quad (i) \end{aligned}$$

$$R_{ik}^s + R_{i,k-1} - R_{ik}^f = R_{ik} \quad \text{for all } i, k, \quad (j)$$

$$\begin{aligned} x_{ijk}, y_{ijk} &\in \{0, 1\}, \quad s_{ik}, f_{ij}, R_{ik}, R_{ik}^s, R_{ik}^f \geq 0 \\ & \quad \text{for all } i, j, k. \end{aligned}$$

Constraints (a), (b), and (c) ensure that each task is assigned to one facility, starts and ends once, and starts and ends on the same facility. Constraint (d) requires events  $1, \dots, 2n$  to occur in chronological order. Constraint (e) enforces the time windows. Constraints (f) and (g) define the finish-time variables in terms of the start-time variables.

The rest of the model encodes the resource constraints. Variable  $R_{ik}$  is the total resource consumption of tasks running on facility  $i$  at the time that event  $k$  occurs. Constraint (h) imposes the upper bound on resource consumption at the time of each event, which is sufficient to impose the bound at all times. Constraint (i) computes the resource consumption  $R_{ik}^s$  of any task starting at the time of event  $k$  and the consumption  $R_{ik}^f$  of any task finishing at the time of event  $k$ . Constraint (j) maintains  $R_{ik}$  at the time of each event in the fashion of an inventory balance equation.

Although it is smaller than (5), the discrete-event model proved to be much harder to solve. We therefore omitted it from the computational results given below.

## 5. Logic-Based Benders Decomposition

Logic-based Benders decomposition applies to problems of the form

$$\begin{aligned} & \text{minimize } f(x, y) \\ & \text{subject to } C(x, y), \\ & \quad x \in D_x, \quad y \in D_y, \end{aligned} \tag{8}$$

where  $C(x, y)$  is a set of constraints containing variables  $x, y$ .  $D_x$  and  $D_y$  denote the domains of  $x$  and  $y$ , respectively. When  $x$  is fixed to a given value  $\bar{x} \in D_x$ , the following subproblem results:

$$\begin{aligned} & \text{minimize } f(\bar{x}, y) \\ & \text{subject to } C(\bar{x}, y), \\ & \quad y \in D_y. \end{aligned} \tag{9}$$

Here,  $C(\bar{x}, y)$  is the constraint that results from fixing  $x = \bar{x}$  in  $C(x, y)$ .

The *inference dual* of (9) is the problem of inferring the tightest possible lower bound on  $f(\bar{x}, y)$  from  $C(\bar{x}, y)$ . It can be written

$$\begin{aligned} & \text{maximize } v \\ & \text{subject to } C(\bar{x}, y) \stackrel{P}{\implies} f(\bar{x}, y) \geq v, \\ & \quad v \in R, \quad P \in \mathcal{P}, \end{aligned} \tag{10}$$

where  $A \stackrel{P}{\implies} B$  means that proof  $P$  deduces  $B$  from  $A$ , and  $\mathcal{P}$  is a family of proofs. The inference dual becomes the linear programming dual when (9) is a linear programming problem and the proofs in  $\mathcal{P}$  correspond to nonnegative linear combinations of the constraints; see Hooker (2000) for details.

The solution of the dual can be viewed as a proof of the tightest possible bound  $\hat{v}$  on  $f(x, y)$  when  $x = \bar{x}$ . The basic idea of Benders decomposition is to use the same proof schema to derive a bound  $B_{\bar{x}}(x)$  for other values of  $x$ . In classical Benders, the same linear combination is used. In general, the bounding function  $B_{\bar{x}}(x)$  should have two properties:

**PROPERTY B1.**  $B_{\bar{x}}(x)$  provides a valid lower bound on  $f(x, y)$  for any given  $x \in D_x$ . That is,  $f(x, y) \geq B_{\bar{x}}(x)$  for any feasible  $(x, y)$  in (8).

**PROPERTY B2.** In particular,  $B_{\bar{x}}(\bar{x}) = \hat{v}$ .

If  $z$  is the objective function value of (8), the valid inequality  $z \geq B_{\bar{x}}(x)$  is a *Benders cut*.

In iteration  $H$  of the Benders algorithm, we solve a master problem whose constraints are the Benders cuts generated so far:

$$\begin{aligned} & \min z \\ & \text{subject to } z \geq B_{x^h}(x), \quad h = 1, \dots, H - 1, \\ & \quad z \in R, \quad x \in D_x. \end{aligned} \tag{11}$$

Here,  $x^1, \dots, x^{H-1}$  are the solutions of the previous  $H - 1$  master problems. Then, the solution  $\bar{x}$  of (11) defines the next subproblem (9).

If we let  $v_1^*, \dots, v_{H-1}^*$  denote the optimal values of the previous  $H - 1$  subproblems, the algorithm continues until the optimal value  $z_H^*$  of the master problem equals  $v^* = \min\{v_1^*, \dots, v_{H-1}^*\}$ . At any point in the algorithm,  $z_H^*$  and  $v^*$  provide lower and upper bounds on the optimal value of the problem.

The following is shown by Hooker (2000). It is convenient to regard (8) or (9) as having an infinite optimal value if it is infeasible.

**THEOREM 1.** *If the bounding function  $B_{\bar{x}}(x)$  satisfies Properties B1 and B2 in each iteration of the Benders algorithm, and  $D_y$  is finite, the Benders algorithm converges to the optimal value of (8) after finitely many steps.*

In the planning and scheduling problem (1), variables  $x, s$  correspond, respectively, to  $x, y$  in (8). Any assignment  $\bar{x}$  of tasks to facilities creates the subproblem

$$\begin{aligned} & \min g(\bar{x}, s) \\ & \text{subject to cumulative}((s_j \mid \bar{x}_j = i), (p_{ij} \mid \bar{x}_j = i), \\ & \quad (c_{ij} \mid \bar{x}_j = i), C_i) \quad \text{for all } i, \\ & \quad r_j \leq s_j \leq d_j - p_{\bar{x}_j j} \quad \text{for all } j, \end{aligned} \tag{12}$$

which decomposes into a separate scheduling problem for each facility  $i$ . After solving the subproblem with a finite-domain CP solver, we generate a Benders cut that becomes part of the master problem (11), which is formulated as a MILP. The domain  $D_s$  can be regarded as finite, as required in Theorem 1, because the CP solver assumes a finite set of start times (such as integers). Release times and deadlines are typically given as integers.

The bounding function  $B_{\bar{x}}(x)$  is generally obtained by examining the type of reasoning that led to a bound for  $x = \bar{x}$  and extending this reasoning to obtain a bound for general  $x$ . In the present context, however, only the primal solution (the schedule itself) is available from the commercial CP solver. We therefore restrict ourselves in this study to Benders cuts that can be formulated without internal information from the CP solver.

## 6. Minimizing Cost

The cost objective presents the simplest case because cost can be computed solely in terms of master problem variables. The subproblem (12) takes the value  $\sum_j F_{x_j j}$  when it is feasible and  $\infty$  when infeasible. Let  $J_{hi} = \{j \mid x_j^h = i\}$  be the set of tasks assigned to facility  $i$  in iteration  $h$ . If there is no feasible schedule for facility  $i$ , the most obvious Benders cut simply rules out assigning this same set  $J_{hi}$  of

tasks to facility  $i$ . In this case, the bounding function takes the form

$$B_{x^h}(x) = \begin{cases} \infty & \text{if the scheduling subproblem on some facility } i \text{ is infeasible, and } x_j^h = x_j \text{ for all } j \in J_{hi}, \\ \sum_j F_{x_j} & \text{otherwise.} \end{cases} \quad (13)$$

The function  $B_{x^h}$  satisfies Property B1 because the cost  $\sum_j F_{x_j}$  is equal to  $B_{x^h}(x)$  for any feasible  $(x, s)$  and is infinite for any infeasible  $(x, s)$ . It satisfies Property B2 because  $B_{x^h}(x^h)$  is the optimal value of the subproblem.

This bound is unnecessarily weak, however, because in many cases a proper subset of the tasks in  $J_{hi}$  are responsible for the infeasibility. Ideally, the scheduler would keep track of which tasks actually play a role in the proof of infeasibility. Because this information is not available, a possibly smaller set  $\bar{J}_{hi}$  of tasks that create infeasibility can be found by a simple greedy algorithm. Initially, let  $\bar{J}_{hi} = J_{hi} = \{j_1, \dots, j_k\}$ . For  $l = 1, \dots, k$ , do the following: Try to schedule the tasks in  $\bar{J}_{hi} \setminus \{j_l\}$  on facility  $i$ , and if there is no feasible schedule, remove  $j_l$  from  $\bar{J}_{hi}$ .  $\bar{J}_{hi}$  can now replace  $J_{hi}$  in (13), and Properties B1 and B2 remain satisfied. Computational testing suggests that, in most cases, re-solving the scheduling problem  $k$  times is well worth the time investment to obtain a stronger bound.

To write the master problem, let  $I_h$  be the set of facilities for which the scheduling problem is infeasible in iteration  $h$ . The master problem (10), written as a 0-1 programming problem, becomes

$$\begin{aligned} & \text{minimize} \sum_{ij} F_{ij} x_{ij} \\ & \text{subject to} \sum_i x_{ij} = 1 \quad \text{for all } j, \quad (a) \\ & \quad \sum_{j \in \bar{J}_{hi}} (1 - x_{ij}) \geq 1 \quad (14) \\ & \quad \text{for all } i \in I_h, h = 1, \dots, H - 1, \quad (b) \\ & \quad \text{relaxation of subproblem,} \quad (c) \end{aligned}$$

where  $x_{ij} \in \{0, 1\}$ , and where constraints (b) are the Benders cuts.

Experience shows that it is important to include a relaxation of the subproblem within the master problem. A straightforward relaxation can be obtained as follows. For any two times  $t_1, t_2$ , let  $J(t_1, t_2)$  be the set of tasks  $j$  whose time windows lie between  $t_1$  and  $t_2$ ; that is,  $[r_j, d_j] \subset [t_1, t_2]$ . If the tasks  $j \in J \subset J(t_1, t_2)$  are assigned to the same facility  $i$ , then clearly the “energy”  $\sum_{j \in J} p_{ij} c_{ij}$  of these tasks can be, at most,  $C_i(t_2 - t_1)$  if they are to be scheduled in the time interval  $[t_1, t_2]$ . This yields the valid inequality

$$\frac{1}{C_i} \sum_{j \in J(t_1, t_2)} p_{ij} c_{ij} x_{ij} \leq t_2 - t_1, \quad (15)$$

**Figure 2.**  $O(n^3)$  algorithm for generating an inequality set  $\mathcal{R}_i$  that relaxes the time window constraints for facility  $i$ .

Let  $\mathcal{R}_i = \emptyset$ .

For  $j = 1, \dots, p$ :

Set  $k' = 0$ .

For  $k = 1, \dots, q$ :

If  $\bar{d}_k \geq \bar{r}_j$  and  $T^i(\bar{r}_j, \bar{d}_k) > T^i(\bar{r}_{j'}, \bar{d}_{k'})$  then

Remove from  $\mathcal{R}_i$  all  $R^i(\bar{r}_{j'}, \bar{d}_k)$  for which  $j' < j$  and  $T^i(\bar{r}_{j'}, \bar{d}_k) \geq T^i(\bar{r}_j, \bar{d}_k)$ .

Add  $R^i(\bar{r}_j, \bar{d}_k)$  to  $\mathcal{R}_i$  and set  $k' = k$ .

*Note.* By convention,  $\bar{d}_0 = -\infty$ .

which we refer to as inequality  $R^i(t_1, t_2)$ . If we let  $\bar{r}_1, \dots, \bar{r}_{n_r}$  be the distinct elements of  $\{r_1, \dots, r_n\}$  in increasing order, and similarly for  $\bar{d}_1, \dots, \bar{d}_{n_d}$ , we have a relaxation consisting of the inequalities

$$R^i(\bar{r}_j, \bar{d}_k), j = 1, \dots, n_r, k = 1, \dots, n_d, \quad (16)$$

for each facility  $i$ . These inequalities serve as the relaxation (c) in (14). There are doubtless stronger relaxations, but we require a linear relaxation that is expressed in terms of the variables  $x_{ij}$ .

Many of these inequalities may be redundant of the others, and if desired they can be omitted from the relaxation. Let

$$T^i(t_1, t_2) = \frac{1}{C_i} \sum_{j \in J(t_1, t_2)} p_{ij} c_{ij} - t_2 + t_1$$

measure the “tightness” of  $R^i(t_1, t_2)$ . It is easily verified that  $R^i(t_1, t_2)$  dominates  $R^i(u_1, u_2)$  whenever  $[t_1, t_2] \subset [u_1, u_2]$  and  $T^i(t_1, t_2) \geq T^i(u_1, u_2)$ . Dominated inequalities can now be removed.

A set of undominated inequalities can be generated for each facility using the algorithm of Figure 2. It has  $O(n^3)$  complexity in the worst case because it is possible that none of the inequalities are eliminated. This occurs, for instance, when each  $r_j = j - 1$ ,  $d_j = j$ , and  $p_{ij} = 2$ . However, the algorithm need only be run once as a preprocessing routine.

In practice, the relaxation can be simplified by supposing that the release times are all  $r_0 = \min_j \{r_j\}$ . Then, the relaxation (c) in (14) consists of

$$R^i(r_0, \bar{d}_k), \quad k = 1, \dots, n_d,$$

for each facility  $i$ . The redundant inequalities can be eliminated by running the simple  $O(n)$  algorithm of Figure 3 for each facility. Similarly, one can suppose that the deadlines are all  $d_0 = \max_j \{d_j\}$  and use the inequalities  $R^i(\bar{r}_j, d_0)$ .

Precedence constraints may be accommodated if they apply only to tasks assigned to the same facility. Thus, if tasks  $j$  and  $k$  must be assigned to the same facility, and  $j$  must precede  $k$ , we add the constraint  $x_j = x_k$  to the master problem (14) and  $t_j + p_{ij} \leq t_k$  for all  $i$  to the subproblem (12).

**Figure 3.**  $O(n)$  algorithm for generating an inequality set  $\mathcal{R}_i$  that relaxes the time window constraints for facility  $i$ , where  $r_0 = \bar{d}_0 = \min_j \{r_j\}$  and  $T^i(r_0, r_0) = 0$ .

Let  $\mathcal{R}_i = \emptyset$ , and set  $j = 0$ .

For  $k = 1, \dots, p_d$ :

If  $T^i(r_0, \bar{d}_k) > T^i(r_0, \bar{d}_j)$  then  
 add  $R^i(r_0, \bar{d}_k)$  to  $\mathcal{R}_i$  and set  $j = k$ .

## 7. Minimizing Makespan

This case is less straightforward because the subproblem is an optimization problem. However, there are relatively simple linear Benders cuts when all tasks have the same release date, and they simplify further when all deadlines are the same. We also use a linear subproblem relaxation that is valid for any set of time windows.

The Benders cuts are based on the following fact:

**LEMMA 2.** Consider a minimum-makespan problem  $P$  in which tasks  $1, \dots, n$  with release time 0 and deadlines  $d_1, \dots, d_n$  are to be scheduled on a single facility  $i$ . Let  $M^*$  be the minimum makespan for  $P$ , and  $\hat{M}$  the minimum makespan for the problem  $\hat{P}$  that is identical to  $P$  except that tasks  $1, \dots, s$  are removed. Then,

$$M^* - \hat{M} \leq \Delta + \max_j \{d_j\} - \min_j \{d_j\}, \quad (17)$$

where  $\Delta = \sum_{j=1}^s p_{ij}$ . In particular, when all the deadlines are the same,  $M^* - \hat{M} \leq \Delta$ .

**PROOF.** Consider any optimal solution of  $\hat{P}$  and extend it to a solution  $S$  of  $P$  by scheduling tasks  $1, \dots, s$  sequentially after  $\hat{M}$ . That is, for  $k = 1, \dots, s$ , let task  $k$  start at time  $\hat{M} + \sum_{j=1}^{k-1} p_{ij}$ . The makespan of  $S$  is  $\hat{M} + \Delta$ . If  $\hat{M} + \Delta \leq \min_j \{d_j\}$ , then  $S$  is clearly feasible for  $P$ , so that  $M^* \leq \hat{M} + \Delta$  and the lemma follows. Now suppose that  $\hat{M} + \Delta > \min_j \{d_j\}$ . This implies

$$\hat{M} + \Delta + \max_j \{d_j\} - \min_j \{d_j\} > \max_j \{d_j\}. \quad (18)$$

Because  $M^* \leq \max_j \{d_j\}$ , (18) implies (17), and again the lemma follows.  $\square$

The bound  $M^* - \hat{M} \leq \Delta$  need not hold when the deadlines differ. Consider, for example, an instance with three tasks where  $(r_1, r_2, r_3) = (0, 0, 0)$ ,  $(d_1, d_2, d_3) = (2, 1, \infty)$ ,  $(p_{i1}, p_{i2}, p_{i3}) = (1, 1, 2)$ ,  $(c_{i1}, c_{i2}, c_{i3}) = (2, 1, 1)$ , and  $C = 2$ . Then, if  $s = 1$ , we have  $M^* - \hat{M} = 4 - 2 > \Delta = p_{i1} = 1$ .

Now consider any given iteration of the Benders algorithm, and suppose for the moment that all the time windows are identical. Let  $J_{hi}$  be the set of tasks assigned to facility  $i$  in a previous iteration  $h$ , and  $M_{hi}^*$  the corresponding minimum makespan incurred by facility  $i$ . The solution of the current master problem removes task  $j \in J_{hi}$  from

facility  $i$  when  $x_{ij} = 0$ . Thus, by Lemma 2, the resulting minimum makespan for facility  $i$  is reduced by at most

$$\sum_{j \in J_{hi}} p_{ij}(1 - x_{ij}), \quad (19)$$

and we therefore have a lower bound on the makespan of facility  $i$ :

$$M_{hi}^* - \sum_{j \in J_{hi}} p_{ij}(1 - x_{ij}).$$

This yields a bounding function

$$B_{x^h}(x) = \max_i \left\{ M_{hi}^* - \sum_{j \in J_{hi}} p_{ij}(1 - x_{ij}) \right\} \quad (20)$$

that bounds the overall makespan and therefore satisfies Property B1. The function satisfies Property B2 as well, because  $B_{x^h}(x^h) = M_{hi}^*$ , which is the optimal subproblem value.

As in the minimum-cost problem, the bound (20) can be strengthened by finding a smaller set  $\bar{J}_{hi}$  that results in the same solution of the scheduling problem. This is again done by a greedy algorithm. Initially, let  $\bar{J}_{hi} = J_{hi} = \{j_1, \dots, j_k\}$ . For  $l = 1, \dots, k$ , do the following: Find a minimum-makespan schedule for the tasks in  $\bar{J}_{hi} \setminus \{j_l\}$  on facility  $i$ , and if the resulting minimum makespan is  $M_{hi}^*$ , remove  $j_l$  from  $\bar{J}_{hi}$ . Now  $\bar{J}_{hi}$  can replace  $J_{hi}$  in (20).

We can write Benders cuts (b) in the master problem as follows:

$$\text{minimize } M$$

$$\text{subject to } \sum_i x_{ij} = 1 \quad \text{for all } j, \quad (a)$$

$$M \geq M_{hi}^* - \sum_{j \in \bar{J}_{hi}} (1 - x_{ij}) p_{ij} \quad (21)$$

$$\text{for all } i, h = 1, \dots, H-1, \quad (b)$$

$$M \geq \frac{1}{C_i} \sum_j c_{ij} p_{ij} x_{ij} \quad \text{for all } i, \quad (c)$$

where  $x_{ij} \in \{0, 1\}$ . The relaxation (c) is similar to that for the minimum-cost problem.

If the deadlines differ (and the release times are still the same), (17) implies that the minimum makespan for facility  $i$  is at least

$$M_{hi}^* - \left( \sum_{j \in \bar{J}_{hi}} p_{ij}(1 - x_{ij}) + \max_{j \in \bar{J}_{hi}} \{d_j\} - \min_{j \in \bar{J}_{hi}} \{d_j\} \right) \quad (22)$$

if one or more tasks are removed, and it is  $M_{hi}^*$  otherwise. The bounding function that results can be linearized to obtain the Benders cuts

$$\begin{aligned} M &\geq M_{hi}^* - \sum_{j \in \bar{J}_{hi}} (1 - x_{ij}) p_{ij} - w_{hi}, \\ w_{hi} &\leq \left( \max_{j \in \bar{J}_{hi}} \{d_j\} - \min_{j \in \bar{J}_{hi}} \{d_j\} \right) \sum_{j \in \bar{J}_{hi}} (1 - x_{ij}), \\ w_{hi} &\leq \max_{j \in \bar{J}_{hi}} \{d_j\} - \min_{j \in \bar{J}_{hi}} \{d_j\}, \end{aligned} \quad \text{for all } i, h = 1, \dots, H-1. \quad (23)$$

When no tasks in  $\bar{J}_{hi}$  are removed from facility  $i$ , the second constraint of (23) forces  $w_{hi}$  to zero, and the bound becomes  $M_{hi}^*$  as required by Property B2. If one or more tasks are removed from facility  $i$ , the bound becomes (22) as desired. The Benders cuts (23) replace (21b) when the deadlines differ and all release times are equal.

## 8. Minimizing Total Tardiness

For this problem, we again assume that all release times are zero. We consider two approaches to formulating Benders cuts, the first of which constructs cuts in a manner similar to those obtained for the minimum-makespan problem. The following lemma provides the basis for these cuts:

**LEMMA 3.** Consider a minimum total tardiness problem  $P$  in which tasks  $1, \dots, n$  have release time 0, due dates  $d_1, \dots, d_n$ , and are to be scheduled on a single facility  $i$ . Let  $T^*$  be the minimum tardiness for this problem, and  $\hat{T}$  the minimum tardiness for the problem  $\hat{P}$  that is identical to  $P$  except that tasks  $1, \dots, s$  are removed. Then,

$$T^* - \hat{T} \leq \sum_{k=1}^s \left( \sum_{j=1}^n p_{ij} - d_k \right)^+. \quad (24)$$

**PROOF.** Consider any optimal solution  $\hat{S}$  of  $\hat{P}$ . We may assume that the makespan of  $\hat{S}$  is at most  $M = \sum_{j=s+1}^n p_{ij}$  because if it is greater than  $M$ , we can move at least one task to an earlier time without increasing the total tardiness of  $\hat{S}$ . To obtain a feasible solution  $S$  for  $P$ , schedule tasks  $1, \dots, s$  sequentially after  $M$ . That is, for  $k = 1, \dots, s$ , let task  $k$  start at time  $M + \sum_{j=1}^{k-1} p_{ij}$ . The tardiness of task  $k$  in  $S$  is at most

$$\left( M + \sum_{j=1}^s p_{ij} - d_k \right)^+ = \left( \sum_{j=1}^n p_{ij} - d_k \right)^+.$$

The total tardiness of  $S$  is therefore at most

$$\hat{T} + \sum_{k=1}^s \left( \sum_{j=1}^n p_{ij} - d_k \right)^+,$$

from which (24) follows.  $\square$

The proof uses the fact that the makespan  $\hat{M}$  of  $\hat{S}$  can be assumed to be, at most,  $M$ . A generally tighter bound could be obtained by assuming that  $\hat{M}$  is, at most, the makespan  $M^*$  of  $P$ 's minimum tardiness solution. Unfortunately, this is not a valid assumption because in exceptional cases  $\hat{M} > M^*$  even though  $\hat{P}$  has fewer tasks than  $P$ . Suppose, for example, that  $n = 4$  and  $s = 1$ , with  $r = (0, 0, 0, 0)$ ,  $d = (5, 3, 3, 6)$ ,  $p = (1, 2, 2, 4)$ ,  $c = (2, 1, 1, 1)$ , and  $C = 2$ . An optimal solution of  $P$  puts  $t = (4, 0, 2, 0)$  with tardiness  $T^* = 1$  and makespan  $M^* = 5$ , but the only optimal solution of the smaller problem  $\hat{P}$  puts  $(t_2, t_3, t_4) = (0, 0, 2)$  with tardiness  $\hat{T} = 0$  and makespan  $\hat{M} = 6 > M^*$ .

Lemma 3 is applied as follows. As before, let  $J_{hi}$  be the set of tasks assigned to facility  $i$  in a previous iteration  $h$ ,

and  $T_{hi}^*$  the corresponding minimum tardiness incurred by facility  $i$ . Because task  $j$  is removed from facility  $i$  when  $x_{ij} = 0$ , the resulting minimum tardiness on facility  $i$  is at least

$$T_{hi}^* - \sum_{k \in J_{hi}} \left( \sum_{j \in J_{hi}} p_{ij} - d_k \right)^+ (1 - x_{ik}).$$

This yields the Benders cuts (b) in the master problem

$$\min T$$

$$\text{subject to } \sum_i x_{ij} = 1 \quad \text{for all } j, \quad (a)$$

$$T \geq \sum_i \left( T_{hi}^* - \sum_{k \in J_{hi}} \left( \sum_{j \in J_{hi}} p_{ij} - d_k \right)^+ (1 - x_{ik}) \right) \quad h = 1, \dots, H-1, \quad (b)$$

relaxation of subproblem.  $(c)$

Unfortunately, these cuts are weak and do not perform well in practice, due to the lack of a tighter bound on  $\hat{M}$ . It appears that stronger cuts require some internal information from the CP solver.

A second approach is to obtain stronger cuts by re-solving the subproblem repeatedly, as done for the minimum-cost and minimum-makespan problems. Several schemes are possible, but we found the following to be effective. Let  $T_i(J)$  be the minimum tardiness on facility  $i$  that results when the tasks in  $J$  are assigned to facility  $i$ , so that  $T_i(J_{hi}) = T_{hi}^*$ . Let  $Z_{hi}$  be the set of tasks in  $J_{hi}$  that can be removed, one at a time, without reducing the minimum tardiness. That is,

$$Z_{hi} = \{j \in J_{hi} \mid T_i(J_{hi} \setminus \{j\}) = T_{hi}^*\}.$$

Finally, let  $T_{hi}^0$  be the minimum tardiness that results from removing all the tasks in  $Z_{hi}$  at once, so that  $T_{hi}^0 = T_i(J_{hi} \setminus Z_{hi})$ . Thus, any or all tasks in  $Z_{hi}$  can be removed from facility  $i$  without reducing the minimum makespan below  $T_{hi}^0$ . This yields a bounding function  $B_{x^h}(x) = \sum_i B_{x^h}^i(x)$ , where

$$B_{x^h}^i(x) = \begin{cases} T_{hi}^0 & \text{if } Z_{hi} \supset \{j \in J_{hi} \mid x_j \neq i\} \neq \emptyset, \\ T_{hi}^* & \text{if } \{j \in J_{hi} \mid x_j \neq i\} = \emptyset, \\ 0 & \text{otherwise.} \end{cases} \quad (25)$$

The function  $B_{x^h}(x)$  satisfies Property B1 by construction. Case (b) of (25) ensures that it satisfies Property B2 as well.

The master problem MILP now becomes

$$\text{minimize } T$$

$$\text{subject to } \sum_i x_{ij} = 1 \quad \text{for all } j, \quad (\text{a})$$

$$T \geq \sum_i T_i, \quad (\text{b})$$

$$T_i \geq T_{hi}^0 - T_{hi}^0 \sum_{j \in J_{hi} \setminus Z_{hi}} (1 - x_{ij}) \quad (26)$$

$$\text{for all } i, h = 1, \dots, H-1, \quad (\text{c1})$$

$$T_i \geq T_{hi}^* - T_{hi}^* \sum_{j \in J_{hi}} (1 - x_{ij}) \quad (26)$$

$$\text{for all } i, h = 1, \dots, H-1, \quad (\text{c2})$$

$$\text{relaxation of subproblem.} \quad (\text{d})$$

The cut (c2) is redundant and can be eliminated for a given  $h, i$  when  $T_{hi}^0 = T_{hi}^*$ . This in fact substantially reduces the size of the master problem because computational testing suggests that  $T_{hi}^0 = T_{hi}^*$  very often.

We employed two relaxations for the master problem (26) because they seem to have somewhat complementary strengths. The first and simpler relaxation is again based on the energy required by tasks. Recall that  $J(t_1, t_2)$  is the set of jobs with time windows between  $t_1$  and  $t_2$ .

**LEMMA 4.** Consider a minimum total tardiness problem in which tasks  $j = 1, \dots, n$  with time windows  $[r_j, d_j]$  are scheduled on a single facility  $i$ , where  $\min_j \{r_j\} = 0$ . The total tardiness incurred by any feasible solution is bounded below by

$$\left( \frac{1}{C_i} \sum_{j \in J(0, d_k)} p_{ij} c_{ij} - d_k \right)^+$$

for each  $k = 1, \dots, n$ .

**PROOF.** For any  $k$ , the last scheduled task in the set  $J(0, d_k)$  can finish no earlier than time  $\hat{T} = (1/C_i) \sum_{j \in J(0, d_k)} p_{ij} c_{ij}$ . Because the last task has a due date no later than  $d_k$ , its tardiness is no less than  $(\hat{T} - d_k)^+$ . Thus, total tardiness is no less than  $(\hat{T} - d_k)^+$ .  $\square$

This gives rise to a relaxation consisting of

$$\begin{aligned} T &\geq \sum_i T_i^L, \\ T_i^L &\geq \frac{1}{C_i} \sum_{j \in J(0, d_k)} p_{ij} c_{ij} x_{ij} - d_k \quad \text{for all } i, k, \\ T_i^L &\geq 0 \quad \text{for all } i. \end{aligned} \quad (27)$$

A second relaxation of the subproblem can be developed on the basis of the following lemma. For each facility  $i$ , let  $\pi_i$  be a permutation of  $\{1, \dots, n\}$  such that  $p_{i\pi_i(1)} c_{i\pi_i(1)} \leq \dots \leq p_{i\pi_i(n)} c_{i\pi_i(n)}$ .

**LEMMA 5.** Consider a minimum-tardiness problem in which tasks  $1, \dots, n$  with time windows  $[r_j, d_j]$  are scheduled on a single facility  $i$ . Assume that  $\min_j \{r_j\} = 0$  and index the tasks so that  $d_1 \leq \dots \leq d_n$ . Then, the total tardiness of any feasible solution is bounded below by  $\underline{T} = \sum_{k=1}^n \underline{T}_k$ , where

$$\underline{T}_k = \left( \frac{1}{C_i} \sum_{j=1}^k p_{i\pi_i(j)} c_{i\pi_i(j)} - d_k \right)^+, \quad k = 1, \dots, n.$$

**PROOF.** Consider any optimal solution of the one-facility minimum-tardiness problem, in which tasks  $1, \dots, n$  are, respectively, scheduled at times  $t_1, \dots, t_n$ . The minimum tardiness is

$$T^* = \sum_{k=1}^n (t_k + p_{ik} - d_k)^+. \quad (28)$$

Let  $\sigma_0(1), \dots, \sigma_0(n)$  be the order in which tasks are scheduled in this solution, so that  $t_{\sigma_0(1)} \leq \dots \leq t_{\sigma_0(n)}$ . For an arbitrary permutation  $\sigma$  of  $\{1, \dots, n\}$ , let

$$\underline{T}_k(\sigma) = \left( \frac{1}{C_i} \sum_{j=1}^k p_{i\pi_i(j)} c_{i\pi_i(j)} - d_{\sigma(k)} \right)^+ \quad (29)$$

and  $\underline{T}(\sigma) = \sum_{k=1}^n \underline{T}_k(\sigma)$ .

We first show that  $T^* \geq \underline{T}(\sigma_0)$ . Because  $\sigma_0$  is a permutation, we can write (28) as

$$T^* = \sum_{k=1}^n (t_{\sigma_0(k)} + p_{i\sigma_0(k)} - d_{\sigma_0(k)})^+.$$

We observe that

$$\begin{aligned} T^* &\geq \sum_{k=1}^n \left( \frac{1}{C_i} \sum_{j=1}^k p_{i\sigma_0(j)} c_{i\sigma_0(j)} - d_{\sigma_0(k)} \right)^+ \\ &\geq \sum_{k=1}^n \left( \frac{1}{C_i} \sum_{j=1}^k p_{i\pi_0(j)} c_{i\pi_0(j)} - d_{\sigma_0(k)} \right)^+ = \underline{T}(\sigma_0), \end{aligned}$$

where the first inequality is based on the energy required by tasks, and the second inequality is due to the definition of  $\pi_i$ .

Now suppose that a bubble sort is performed on the integers  $\sigma_0(1), \dots, \sigma_0(n)$  so as to put them in increasing order, and let  $\sigma_0, \dots, \sigma_p$  be the resulting series of permutations. Thus,  $(\sigma_p(1), \dots, \sigma_p(n)) = (1, \dots, n)$ , and  $\sigma_{p+1}$  is obtained from  $\sigma_p$  by swapping two adjacent terms  $\sigma_p(k)$  and  $\sigma_p(k+1)$ , where  $\sigma_p(k) > \sigma_p(k+1)$ . This means that  $\sigma_p$  and  $\sigma_{p+1}$  are the same except that  $\sigma_{p+1}(k) = \sigma_p(k+1)$  and  $\sigma_{p+1}(k+1) = \sigma_p(k)$ . Because  $T^* \geq \underline{T}(\sigma_0)$  and  $\underline{T}(\sigma_p) = \underline{T}$ , to prove the theorem it suffices to show  $\underline{T}(\sigma_0) \geq \dots \geq \underline{T}(\sigma_p)$ .

Thus, we consider any two adjacent permutations  $\sigma_p, \sigma_{p+1}$  and show that  $\underline{T}(\sigma_p) \geq \underline{T}(\sigma_{p+1})$ . We observe that

$$\begin{aligned}\underline{T}(\sigma_p) &= \sum_{j=1}^{k-1} \underline{T}_j(\sigma_p) + \underline{T}_k(\sigma_p) \\ &\quad + \underline{T}_{k+1}(\sigma_p) + \sum_{j=k+2}^n \underline{T}_j(\sigma_p),\end{aligned}\tag{30}$$

$$\begin{aligned}\underline{T}(\sigma_{p+1}) &= \sum_{j=1}^{k-1} \underline{T}_j(\sigma_p) + \underline{T}_k(\sigma_{p+1}) \\ &\quad + \underline{T}_{k+1}(\sigma_{p+1}) + \sum_{j=k+2}^n \underline{T}_j(\sigma_p).\end{aligned}$$

Using (29), we note that  $\underline{T}_k(\sigma_p) = (a - B)^+$ ,  $\underline{T}_{k+1}(\sigma_p) = (A - b)^+$ ,  $\underline{T}_k(\sigma_{p+1}) = (a - b)^+$ , and  $\underline{T}_{k+1}(\sigma_{p+1}) = (A - B)^+$  if we set

$$\begin{aligned}a &= \frac{1}{C_i} \sum_{j=1}^k p_{i\pi_i(j)} c_{i\pi_i(j)}, & A &= \frac{1}{C_i} \sum_{j=1}^{k+1} p_{i\pi_i(j)} c_{i\pi_i(j)}, \\ b &= d_{\sigma_p(k+1)}, & B &= d_{\sigma_p(k)}.\end{aligned}$$

Note that  $a \leq A$ . Also,  $b \leq B$  because  $\sigma_p(k) > \sigma_p(k+1)$  and  $d_1 \leq \dots \leq d_n$ . From (30), we have

$$\begin{aligned}\underline{T}(\sigma_p) - \underline{T}(\sigma_{p+1}) &= (a - B)^+ + (A - b)^+ \\ &\quad - (a - b)^+ - (A - B)^+.\end{aligned}$$

It is straightforward to check that this quantity is always non-negative when  $a \leq A$  and  $b \leq B$ . The theorem follows.  $\square$

The bound of Lemma 5 can be written in terms of the variables  $x_{ik}$ :

$$\sum_{k=1}^n \underline{T}'_{ik} x_{ik},\tag{31}$$

where

$$\underline{T}'_{ik} \geq \frac{1}{C_i} \sum_{j=1}^k p_{i\pi_i(j)} c_{i\pi_i(j)} x_{i\pi_i(j)} - d_k, \quad k = 1, \dots, n,$$

and  $\underline{T}'_{ik} \geq 0$ . The variable  $x_{ik}$  appears in (31) because the term  $\underline{T}'_{ik}$  should occur only for those tasks  $j$  that are assigned to facility  $i$  (i.e.,  $x_{ik} = 1$ ). We linearize the bound by writing it as

$$\sum_{k=1}^n \underline{T}_{ik},\tag{32}$$

where

$$\begin{aligned}\underline{T}_{ik} &\geq \frac{1}{C_i} \sum_{j=1}^k p_{i\pi_i(j)} c_{i\pi_i(j)} x_{i\pi_i(j)} - d_k - (1 - x_{ik}) U_{ik}, \\ &\quad k = 1, \dots, n,\end{aligned}\tag{33}$$

and  $\underline{T}_{ik} \geq 0$ . The big-M term  $U_{ik}$  is given by

$$U_{ik} = \frac{1}{C_i} \sum_{j=1}^k p_{i\pi_i(j)} c_{i\pi_i(j)} - d_k.$$

Note that although  $U_{ik}$  can be negative, the right-hand side of (33) is never positive when  $x_{ik} = 0$ . Finally, to obtain a relaxation of the subproblem, we sum (32) over all facilities and write

$$T \geq \sum_{i=1}^m \sum_{k=1}^n \underline{T}_{ik}.\tag{34}$$

The relaxation (c) of the master problem now consists of two relaxations, the first of which is (27), and the second (34) together with (33) for  $i = 1, \dots, m$ . The second relaxation is valid only when tasks are indexed so that  $d_1 \leq \dots \leq d_n$ .

## 9. Problem Generation

Random instances were generated as follows for minimum-cost and minimum-makespan problems. The capacity limit was set to  $C_i = 10$  for each facility  $i$ . For each task  $j$ ,  $c_{ij}$  was assigned the same random value for all facilities  $i$  and drawn from a uniform distribution on  $[1, 10]$ . For instances with  $n$  tasks and  $m$  facilities, the processing time  $p_{ij}$  of each task  $j$  on facility  $i$  was drawn from a uniform distribution on  $[i, 10i]$ . Thus, facility 1 tends to run about  $i$  times faster than facility  $i$  for  $i = 1, \dots, m$ . Because the average of  $10i$  over  $m$  facilities is  $5(m+1)$ , the total processing time of all tasks is roughly proportional to  $5n(m+1)$ , or about  $5n(m+1)/m$  per facility. The release dates were set to zero, and the deadline for every task was set to  $\alpha L$  (rounded to the nearest integer), where  $L = 5n(m+1)/m$ . We used  $\alpha = 1/3$  for the minimum-cost and minimum-makespan problems, which results in a deadline that is loose enough to permit feasible solutions, but tight enough so that tasks are reasonably well distributed over the facilities in minimum-cost solutions. In minimum-cost problems, the cost  $F_{ij}$  is drawn from a uniform distribution on  $[2(m-i+1), 20(m-i+1)]$ , so that faster facilities tend to be more expensive.

No precedence constraints were used, which tends to make the scheduling portion of the problem more difficult. The wide variation in facility speeds tends to put the Benders approach at a disadvantage because the faster facilities receive more tasks and require disproportionately more computation to solve the scheduling problem.

For minimum-tardiness problems, we set the release dates to zero and drew the due dates from a uniform distribution on the interval  $[\frac{1}{4}\alpha L, \alpha L]$ , again using  $\alpha = 1/3$ . We found that when the processing time for facility  $i$  is drawn from  $[i, 10i]$ , the wide range of facility speeds often results in solutions in which nearly all tasks are assigned to the fastest facility. We therefore generated problems on three facilities in which the processing time is drawn from

**Table 1.** Computation times in seconds for the minimum-cost and minimum-makespan problems, using MILP, CP, and logic-based Benders methods.

Facilities	Tasks	Minimum cost			Minimum makespan

*Notes.* Each time represents the average of five instances. Computation was cut off after two hours (7,200 seconds), and a + indicates that this occurred for at least one of the five problems. The test problems are  $cNjMmK$ , where  $N$  is the number of tasks,  $M$  is the number of facilities, and  $K$  is the problem number ( $K = 1, \dots, 5$ ).

\*CPLEX ran out of memory on one or more problems, which are omitted from the average time.

a uniform distribution on [2, 20], [2, 25], and [2, 30] for the three facilities, respectively. For 22 or more tasks we used the intervals [5, 20], [5, 25], and [5, 30] because otherwise the minimum tardiness tends to be zero in the larger problems.

To test the minimum-cost and minimum-makespan methods on problems with deadlines, we generated instances similar to the minimum-tardiness problems, but with  $\alpha = 1/2$  rather than  $\alpha = 1/3$  to avoid infeasible instances. We also generated instances in which the release times differ for each task. In these instances, the release time  $r$  is drawn uniformly from the interval  $[0, \alpha L]$ , and the deadline is drawn uniformly from  $[r + \frac{1}{4}\alpha L, r + \alpha L]$ .

## 10. Computational Results

We solved randomly generated problems with MILP (using CPLEX), CP (using the ILOG Scheduler), and the logic-based Benders method. All three methods were implemented with OPL Studio, using the OPL script language. The CP problems were solved with the assignAlternatives and setTimes options, and the CP subproblems of the Benders method were solved with the setTimes option. Both result in substantially better performance.

Table 1 displays computational results for the minimum-cost and minimum-makespan problems on two, three, and four facilities. The CP solver is consistently faster than MILP on minimum-cost problems. However, CP is unable to solve most problems with more than 16 tasks within two hours of computation time.

The Benders method is substantially faster than both CP and MILP. Its advantage increases rapidly with problem size, reaching some three orders of magnitude relative to CP for 16 or 18 tasks. Presumably, the advantage would be greater for larger problems.

On minimum-makespan problems, CP and MILP appear to be roughly competitive overall, with CP generally faster on two-facility problems and MILP faster on three- and four-facility problems. Again, the Benders method is considerably faster than both CP and MILP, with speedups ranging between two and three orders of magnitude for problems small enough to be solved by CP or MILP. As before, the speedup increases with the problem size.

As the number of tasks increases, the Benders subproblems in the minimum-cost and minimum-makespan problems eventually reach a size at which the computation time for the scheduling subproblem explodes. This point is reached later when there are more facilities because the subproblems are smaller when the tasks are spread over

**Table 2.** Computation times in seconds for the minimum-cost and minimum-makespan problems, using MILP and the Benders method.

Tasks	Minimum cost Different deadlines			Minimum cost Different deadlines and release times			Minimum makespan Different deadlines		
	CP	MILP	Benders	CP	MILP	Benders	CP	MILP	Benders
14	1.2	93	0.17	0.95	0.82	0.25	7.1	223	4.4

28		4,102**	1,681+		3,032+	4.3			2,709+

*Notes.* Each time represents the average of five instances. Computation was cut off after two hours (7,200 seconds), and a + indicates that this occurred for at least one of the five problems. The problems with different deadlines are  $dNjMmK$ , and those with different deadlines and release times are  $dfNjMmK$ .

\*CPLEX ran out of memory on one problem, which is omitted from the average time.

\*\*CPLEX ran out of memory on two problems, which are omitted from the average time.

\*\*\*CPLEX ran out of memory on three problems, which are omitted from the average time.

more facilities. In practice, precedence constraints or other side constraints could accelerate the solution of the scheduling subproblems and allow the solution of larger problems.

Table 2 reports tests of CP, MILP and Benders on (a) minimum-cost problems in which the tasks have different deadlines, (b) minimum-cost problems in which they have different release times and different deadlines, and (c) minimum-makespan problems in which the tasks have different deadlines. MILP is generally faster than CP on these problems.

The advantage of the Benders method remains substantial. It is at least as great as before on problems (b). MILP terminated due to insufficient memory on several of the problems (a), thus removing the instances on which it is likely to run longest. The speedup appears to be somewhat less than before on problems (c), but this is due primarily to a single outlier with 20 tasks that Benders could not solve in two hours.

Table 3 investigates how the Benders method scales up to a larger number of facilities when the average number of tasks per facility is fixed to five. The random instances are generated so that the fastest facility is roughly twice as fast as the slowest facility, with the other facility speeds spaced evenly in-between. Because the subproblems remain relatively small as the problem size increases, it is possible to accommodate more tasks than in Tables 1 and 2. In this case, the master problem (rather than the subproblem) dominates the computational task in larger problems and eventually becomes too hard to solve.

Table 3 suggests that the Benders method scales up better for minimum-cost problems than for minimum-makespan problems. However, even when it fails to solve a makespan

**Table 3.** Computation times in seconds for the minimum-cost and minimum-makespan problems, using the Benders method.

\*\*\*The best-known solution is 128, obtained using a slightly weaker relaxation.

problem optimally, it obtains a feasible solution and a fairly tight lower bound on the optimal value. The bound steadily improves as the algorithm runs. Table 4 displays the bounds obtained for the minimum-makespan problems of Table 3 that were not solved to optimality.

Table 5 shows computational results for minimum-tardiness problems on three facilities using CP, MILP, and Benders. Because problem difficulty tends to increase rapidly with minimum tardiness, the table shows results for

individual problem instances and indicates the minimum tardiness for each. The instances are listed in order of minimum tardiness for each problem size.

The minimum-tardiness problems are more readily solved by MILP than by CP. Nonetheless, the Benders method is faster than MILP for nearly all problem instances. The advantage of the hybrid approach is not as great as for the minimum-cost and minimum-makespan problems. However, for larger problems (16 or more tasks)

**Table 6.** Effect of the subproblem relaxation on performance of the Benders method.

Tasks	Minimizing tardiness:		Problem no.
	With relaxation	Without relaxation	
16	1.4	4.4	2

that the Benders method solved to optimality, the average speedup factor relative to MILP is 25. This is actually an underestimate because the MILP solver was cut off after two hours. Table 6 shows that the relaxations based on Lemmas 4 and 5 are key to the success of the Benders method.

Despite its better performance, the Benders method does not significantly enlarge the class of tardiness problems that can be solved to optimality. It failed to solve six of the 40 instances to optimality, only a modest improvement over the 10 that were intractable for MILP. On problems too large to solve optimally, however, it finds much better solutions than MILP finds within two hours. The Benders method also finds a lower bound on the optimal value that steadily increases with the number of iterations. The lower bounds are rather weak for the instances solved here, but they are tighter than the lower bound of zero obtained from the continuous relaxation of the MILP model.

## 11. Conclusions and Future Research

We find that logic-based Benders decomposition can improve substantially on the state of the art for the solution of planning and scheduling problems. In the case of minimum-cost and minimum-makespan problems, the Benders method is several orders of magnitude faster than either CP or MILP and solves larger problem instances to optimality.

The speedup is not nearly as great on the minimum-tardiness problems, but significant nonetheless. The Benders method does not solve significantly larger problems to optimality, but obtains much better solutions than MILP for instances too large to solve optimally.

In fact, an important advantage of the Benders approach is that it can be terminated early while still yielding a feasible solution, as well as a lower bound on the optimal value that improves steadily as the algorithm runs. (This does not apply to the minimum-cost problems, for which all intermediate solutions are infeasible.)

Future research should address several issues. One is whether effective Benders cuts can be developed for minimum-makespan and minimum-tardiness problems in which tasks have different release dates. In addition, implementation of a branch-and-check approach to solving the master problem could significantly improve performance, particularly on problems in which the master problem dominates the computational burden.

A fundamental issue is whether access to dual information from the CP scheduler (results of edge finding, etc.) would result in more effective Benders cuts, and how these cuts would be derived. This is particularly important for the tardiness problem, where the Benders cuts used here are rather weak.

A related issue is how to incorporate strong cuts in the master problem without generating a large number of constraints. Computational experience with the tardiness problems, for instance, suggests that stronger cuts could have been generated with little additional effort by solving a greater number of modified subproblems in each iteration. Each of the strong cuts, however, involves a logical condition that requires a large number of linear inequalities (many with “big-M” coefficients) to formulate it in the MILP master problem. Solution of the master problem bogs down as the cuts accumulate.

This suggests that rather than solving the master problem in the form of a MILP, it may be more effective to apply an algorithm that accommodates more complex logical constraints. This, in combination with a branch-and-check strategy, could result in a more robust class of Benders methods.
